Abstract

Environmental DNA (eDNA) metabarcoding can identify terrestrial taxa utilising aquatic habitats alongside aquatic communities, but terrestrial species' eDNA dynamics are understudied. We evaluated eDNA metabarcoding for monitoring semi-aquatic and terrestrial mammals, specifically nine species of conservation or management concern, and examined spatiotemporal variation in mammal eDNA signals. We hypothesised eDNA signals would be stronger for semi-aquatic than terrestrial mammals, and at sites where individuals exhibited behaviours. In captivity, we sampled waterbodies at points where behaviours were observed ('directed' sampling) and at equidistant intervals along the shoreline ('stratified' sampling). We surveyed natural ponds (N = 6) where focal species were present using stratified water sampling, camera traps, and field signs. eDNA samples were metabarcoded using vertebrate-specific primers. All focal species were detected in captivity. eDNA signal strength did not differ between directed and stratified samples across or within species, between semi-aquatic or terrestrial species, or according to behaviours. eDNA was evenly distributed in artificial waterbodies, but unevenly distributed in natural ponds. Survey methods deployed at natural ponds shared three species detections. Metabarcoding missed badger and red fox recorded by cameras and field signs, but detected small mammals these tools overlooked, e.g. water vole. Terrestrial mammal eDNA signals were weaker and detected less frequently than semi-aquatic mammal eDNA signals. eDNA metabarcoding could enhance mammal monitoring through large-scale, multi-species distribution assessment for priority and difficult to survey species, and provide early indication of range expansions or contractions. However, eDNA surveys need high

46   spatiotemporal resolution and metabarcoding biases require further investigation before

47   routine implementation.

48

1. Introduction

Mammals are a highly threatened taxon, with 25% of species at risk of extinction globally due to harvesting, habitat degradation/loss, non-native species or perception as pests (Visconti et al., 2011). Most species lack long-term, systematic monitoring, with survey efforts biased towards rare species (Massimino, Harris, & Gillings, 2018). Data deficiency prevents robust estimation of mammalian range expansions/declines and population trends (Bland, Collen, Orme, & Bielby, 2015). Therefore, effective and evidence-based strategies for mammal conservation and management are urgently needed (Mathews et al., 2018).

Many mammals are nocturnal and elusive thus monitoring requires non-invasive, observational methods such as camera traps and field signs, e.g. footprints, scat (Caravaggi et al., 2018; Harris & Yalden, 2004; Kinoshita et al., 2019; Sadlier, Webbon, Baker, & Harris, 2004). Camera trapping is cost-efficient, standardised, reproducible, and produces data suited to site occupancy modelling, but only surveys a fraction of large, heterogeneous landscapes. Trap placement can substantially influence species detection probabilities, and traps often miss small species (Burton et al., 2015; Caravaggi et al., 2018; Ishige et al., 2017; Leempoel, Hebert, & Hadly, 2019). Field sign surveys are inexpensive, but resource-intensive for broad geographic coverage (Kinoshita et al., 2019; Sadlier et al., 2004). Species can have similar footprints and scat, increasing the potential for misidentification (Franklin et al., 2019; Harris & Yalden, 2004). Mammal survey methods can be species-specific, thus multiple methods are necessary for large-scale, multi-species monitoring schemes (Massimino et al., 2018; Sales et al., 2019).

Environmental DNA (eDNA) analysis is a recognised tool for rapid, non-invasive, cost-

74   efficient biodiversity assessment across aquatic and terrestrial ecosystems (Deiner et al., 2017).

75   Organisms transfer genetic material to their environment via secretions, excretions, gametes,

76   blood, or decomposition, which can be isolated from environmental samples (Thomsen &

77   Willerslev, 2015). Studies using eDNA analysis to target specific semi-aquatic and terrestrial

78   mammals have employed PCR or quantitative PCR (qPCR) (e.g. Franklin et al., 2019; Lugg,

79   Griffiths, van Rooyen, Weeks, & Tingley, 2017; Rodgers & Mock, 2015; Thomsen et al., 2012;

80   Williams, Huyvaert, Vercauteren, Davis, & Piaggio, 2018). eDNA metabarcoding can screen

81   entire communities using PCR combined with high-throughput sequencing (Deiner et al., 2017;

82   Thomsen & Willerslev, 2015), but mammalian assessments are uncommon (Klymus, Richter,

83   Thompson, & Hinck, 2017; Kinoshita et al., 2019; Leempoel et al., 2019; Sales et al., 2019; Ushio

84   et al., 2017). Tropical mammal assemblages have been obtained by metabarcoding invertebrate

85   blood meals (e.g. Tessler et al., 2018) and salt licks (Ishige et al., 2017), but samples from the

86   physical environment have tremendous potential to reveal mammal biodiversity over broad

87   spatiotemporal scales (Sales et al., 2019; Ushio et al., 2017).

88   In aquatic ecosystems, eDNA metabarcoding has predominantly been applied to

89   characterise fish (e.g. Evans et al., 2017; Hänfling et al., 2016; Lawson Handley et al., 2018;

90   Valentini et al., 2016) and amphibian (e.g. Bálint et al., 2018; Valentini et al., 2016)

91   communities. However, mammals also leave eDNA signatures in water that metabarcoding can

92   detect (Harper et al., 2019; Klymus et al., 2017; Sales et al., 2019; Ushio et al., 2017). Ponds in

93   particular provide drinking, foraging, dispersive, and reproductive opportunities for semi-

94   aquatic and terrestrial mammals (Klymus et al., 2017). Samples from these waterbodies could

95   uncover biodiversity present in the wider environment (Deiner et al., 2017; Harper et al., 2019).

96   Drinking is a major source of eDNA deposition due to the release of saliva, but mammals may

97   also swim, wallow, urinate or defecate in water (Rodgers & Mock, 2015; Ushio et al., 2017;

98   Williams et al., 2018). Furthermore, arboreal mammals may use ponds less than semi-aquatic

99   and ground-dwelling species, non-territorial mammals may visit ponds less than territorial

100 species, and group-living species may deposit more eDNA than solitary species (Williams et al.,

101 2018). Despite evidence for eDNA deposition by semi-aquatic and terrestrial mammals in

102 freshwater ecosystems, little is known about the influence of mammal behaviour on the

103 distribution and strength of the eDNA signal left behind (defined here as proportional read

104 counts).

105   In this study, we conducted two experiments under artificial and natural conditions to

106 evaluate eDNA metabarcoding of pond water as a tool for monitoring semi-aquatic, ground-

107 dwelling, and arboreal mammals of conservation or management concern. The first

108 experiment, carried out on nine focal species housed at two wildlife parks, examined the role of

109 sampling strategy, mammal lifestyle, and mammal behaviour on eDNA detection and signal

110 strength under artificial conditions. Mammal eDNA detection is expected from enclosure water

111 that is frequently used by individuals for drinking, swimming and bathing. We hypothesised

112 that: (1) eDNA would be unevenly distributed, thus directed sampling would yield stronger

113 eDNA signals (i.e. higher proportional read counts) for mammals than stratified sampling; (2)

114 semi-aquatic mammals would have stronger eDNA signals than ground-dwelling or arboreal

115 mammals; and (3) mammal behaviours involving water contact would generate stronger eDNA

116 signals. The second experiment validated eDNA metabarcoding against camera trapping and

117 field sign searches for mammal identification at natural ponds, and investigated spatiotemporal

118 variation in mammal eDNA signals. Mammal eDNA detection is unpredictable at natural

119 waterbodies that can be extensive, subject to environmental fluctuations, and used rarely or

120 not at all by individuals. We hypothesised that: (1) eDNA metabarcoding would detect more

121 mammals than camera trapping or field signs; (2) semi-aquatic mammals would be readily

122 detected and their eDNA evenly distributed in ponds in comparison to terrestrial mammals; and

123 (3) temporal sampling would reveal that terrestrial mammal eDNA is detectable for short

124 periods in comparison to fully aquatic vertebrates.

125

126

127 ## 2. Materials and methods

128

129 **2.1 Study species**

130

131 We studied nine mammal species that are the focus of European conservation or management

132 (Mathews et al., 2018): European water vole (*Arvicola amphibius*), European otter (*Lutra lutra*),

133 Eurasian beaver (*Castor fiber*), European hedgehog (*Erinaceus europaeus*), European badger

134 (*Meles meles*), red deer (*Cervus elaphus*), Eurasian lynx (*Lynx lynx*), red squirrel (*Sciurus

135 vulgaris*), and European pine marten (*Martes martes*). Water vole, otter, red squirrel, pine

136 marten and hedgehog are UK Biodiversity Action Plan species (Joint Nature Conservation

137 Committee, 2018). Water vole, otter, and beaver are semi-aquatic, red squirrel and pine

138 marten are arboreal, and the other species are ground-dwelling. Badger and red deer live in

139 groups whereas the other species are predominantly solitary.

140

2.2 Experiment 1: eDNA detection and signal strength in artificial systems

142

Behavioural observation and eDNA sampling were conducted between 18th – 21st September

2017 at Wildwood Trust (WT), Kent, England, and 10th – 11th October 2017 at Royal Zoological

Society of Scotland (RZSS) Highland Wildlife Park (HWP), Kingussie, Scotland. Sixteen categories

of behaviour were defined based on potential contact with waterbodies and species lifestyle,

and the frequency and duration of behaviours recorded (Table 1, Appendix A: Table A1). The

number of individuals in each enclosure was recorded alongside waterbody size (Table 2).

Beaver, lynx, red deer, and red squirrel were present at both wildlife parks, whereas other

captive species were only present at WT. Each species was observed for one hour on two

separate occasions except nocturnal mammals (badger and beaver), which were observed

overnight using camera traps (Bushnell Trophy Cam Standard, Bushnell Corporation, KS, USA).

One camera trap per enclosure was positioned perpendicular to the ground (1 m height, 2 m

from shoreline) to capture water and shoreline. Cameras took 30 s videos (1920 x 1080) when

triggered (30 s interval between triggers) at high sensitivity. Behavioural observation was not

undertaken for WT water voles as animals were under quarantine or HWP red squirrels as

individuals were wild. Photos of waterbodies in animal enclosures are provided in Appendix B.

Water samples were collected from enclosures within 3 hrs of the second behavioural

observation period. Up to six directed or stratified samples were collected, but sample number

varied by species according to waterbody size and observed behaviours (Tables A1, A2).

Enclosure drinking containers were also sampled and classed as 'other' samples. Bathing and

162   drinking bowls were sampled where enclosures contained no artificial waterbodies (WT water

163   vole, red squirrel, and hedgehog). The HWP beaver enclosure was empty for 24 hrs before

164   sampling. Water was sampled from a RZSS Edinburgh Zoo (EZ) enclosure containing beavers

165   and classed as 'other'. A sample was collected from a water bath in the HWP woods to capture

166   wild red squirrels and classed as 'other'.

167   Directed samples (2 L surface water taken approximately where behaviours were

168   observed) were collected before stratified samples (2 L surface water [8 x 250 ml pooled

169   subsamples] taken at equidistant points [access permitting] around the waterbody perimeter)

170   to minimise disturbance to the water column and cross-contamination risk. Samples were

171   collected using sterile Gosselin™ HDPE plastic bottles (Fisher Scientific UK Ltd, UK) and

172   disposable gloves. A field blank (1 L molecular grade water [MGW]) was taken into each species

173   enclosure, opened, and closed before artificial water sources were sampled. Samples (n = 80)

174   collected from WT and HWP were transported alongside field blanks (n = 13) in sterile

175   coolboxes with ice packs to the University of Kent (UoK) and EZ respectively, where ice was

176   added to coolboxes.

177   Samples and blanks were vacuum-filtered within 6 hrs of collection in a UoK wet

178   laboratory and within 24 hrs of collection in an EZ staff room. Surfaces and equipment were

179   sterilised before, during, and after set-up in temporary work areas. Surfaces and vacuum

180   pumps were wiped with 10% v/v chlorine-based commercial bleach (Elliott Hygiene Ltd, UK)

181   solution. Non-electrical equipment was immersed in 10% bleach solution for 10 minutes,

182   followed by 5% v/v MicroSol detergent (Anachem, UK), and rinsed with purified water. Up to

183   500 ml of each 2 L sample was vacuum-filtered through sterile 0.45 μm mixed cellulose ester

184   membrane filters with pads (47 mm diameter; Whatman, GE Healthcare, UK) using Nalgene™

185   filtration units. One hour was allowed for each sample to filter and a second filter used if

186   clogging occurred. A filtration blank (1 L MGW) was processed during each filtration round (n =

187   12), and equipment sterilised after each filtration round. After 500 ml had filtered or one hour

188   had passed, filters were removed from pads using sterile tweezers, placed in sterile 47 mm

189   petri dishes (Fisher Scientific UK Ltd, UK), sealed with parafilm (Sigma-Aldrich Company Ltd,

190   UK), and stored at -20 °C. The total water volume filtered per sample was recorded for

191   downstream analysis (Table A2; Fig. A1).

192

193   **2.3 Experiment 2: eDNA detection and signal strength in natural systems**

194

195   At three sites where focal species were present based on cumulative survey data, we selected

196   two ponds (range 293-5056 m^2, average 1471 m^2) within 4 km of each other. The Bamff Estate

197   (BE), Alyth, Scotland, was selected for beaver, otter, badger, red deer, and red squirrel, but roe

198   deer (*Capreolus capreolus*) and red fox (*Vulpes vulpes*) were also present. Otter, water vole, and

199   badger were present at Tophill Low Nature Reserve (TLNR), Driffield, East Yorkshire, alongside

200   American mink (*Neovison vison*), stoat (*Mustela erminea*), weasel (*Mustela nivalis*), rabbit

201   (*Oryctolagus cuniculus*), brown hare (*Lepus europaeus*), red fox, roe deer, and grey squirrel

202   (*Sciurus carolinensis*). We selected Thorne Moors (TM), Doncaster, South Yorkshire, for red deer

203   and badger, but stoat, weasel, red fox, roe deer, and Reeve's muntjac (*Muntiacus reevesi*) were

204   also present. Camera traps (Bushnell Trophy Cam Standard/Aggressor, Bushnell Corporation,

205   KS, USA) were deployed at TM (one per pond) and BE (three per pond) one week prior to eDNA

206 sampling and collected once sampling was completed. At TLNR, camera traps (two to three per

207 pond) were deployed one day before a 5-day period of eDNA sampling and collected one week

208 after sampling was completed. Camera traps were positioned perpendicular to the ground (1 m

209 height, 0.3-1 m from shoreline) to capture water and shoreline. Cameras took three

210 photographs (5 megapixel) when triggered (3 s interval between triggers) at high sensitivity.

211 Ten stratified samples were collected from the shoreline of each pond (TM: 17th April

212 2018; BE: 20th April 2018; TLNR: 23rd – 27th April 2018) and a field blank (1 L MGW) included as

213 in Experiment 1. TLNR ponds were sampled every 24 hrs over 5 days to investigate

214 spatiotemporal variation in mammal eDNA signals. TM and TLNR samples were transported on

215 ice in sterile coolboxes to the University of Hull (UoH) eDNA facility, and stored at 4 °C. BE

216 samples were transported in sterile coolboxes with ice packs to BE accommodation. Surfaces

217 and equipment were sterilised before, during, and after set-up as in Experiment 1. Samples (n =

218 140) and field blanks (n = 14) were vacuum-filtered within 4 hrs of collection as in Experiment 1

219 with minor modifications to maximise detection probability as follows. The full 2 L of each

220 sample was vacuum-filtered where possible, two filters were used for each sample, and

221 duplicate filters were stored in one petri dish at -20 °C. A filtration blank (1 L MGW) was

222 processed during each filtration round (n = 21). The total water volume filtered per sample was

223 recorded (Table A3).

224

2.4 DNA extraction

DNA was extracted within 2 weeks of filtration at the UoH eDNA facility using the Mu-DNA water protocol (Sellers, Di Muri, Gómez, & Hänfling, 2018). The full protocol is available at: https://doi.org/10.17504/protocols.io.qn9dvh6. Duplicate filters from samples in Experiment 1 were lysed independently and the lysate from each loaded onto one spin column. As more samples were collected in Experiment 2, duplicate filters were co-extracted by placing both in a single tube for bead milling. An extraction blank, consisting only of extraction buffers, was included for each round of DNA extraction (n = 17). Eluted DNA (100 µl) was stored at -20 °C until PCR amplification.

2.5 eDNA metabarcoding

Our eDNA metabarcoding workflow is fully described in Appendix A. Briefly, we performed nested metabarcoding using a two-step PCR protocol, where Multiplex Identification (MID) tags were included in the first and second PCR for sample identification (Kitson et al., 2019). The first PCR amplified eDNA in triplicate with published 12S ribosomal RNA (rRNA) primers 12S-V5-F (5'-ACTGGGATTAGATACCCC-3') and 12S-V5-R (5'-TAGAACAGGCTCCTCTAG-3') (Riaz et al., 2011). Harper et al. (2018) validated these primers *in silico* for UK vertebrates, and found 91/112 mammal species listed on the Natural History Museum Checklist of Mammalia v1 (subspecies excluded) could be distinguished. Nine indistinguishable species lacked reference sequences, whereas 12 had reference sequences but did not amplify. PCR positive controls (two per PCR

247 plate; *n* = 16) were exotic cichlid (*Maylandia zebra*) DNA (0.05 ng/µl), and PCR negative controls

248 (two per PCR plate; *n* = 16) were MGW (Fisher Scientific UK Ltd, UK). PCR products were pooled

249 to create sub-libraries (Fig. A2) and purified with Mag-BIND® RxnPure Plus magnetic beads

250 (Omega Bio-tek Inc, GA, USA), following the double size selection protocol established by

251 Bronner et al. (2009). Ratios of 0.9x and 0.15x magnetic beads to 100 µL of each sub-library

252 were used. Eluted DNA (30 µL) was stored at -20 °C until the second PCR could be performed.

253 The second PCR bound pre-adapters, MID tags, and Illumina adapters to the sub-libraries. PCR

254 products were purified with Mag-BIND® RxnPure Plus magnetic beads (Omega Bio-tek Inc, GA,

255 USA), following the double size selection protocol established by Bronner et al. (2009). Ratios of

256 0.7x and 0.15x magnetic beads to 50 µL of each sub-library were used. Eluted DNA (30 µL) was

257 stored at 4 °C until quantification and normalisation. The library was purified again, quantified

258 by qPCR using the NEBNext® Library Quant Kit for Illumina® (New England Biolabs® Inc., MA,

259 USA), and fragment size (330 bp) and removal of secondary product verified using an Agilent

260 2200 TapeStation and High Sensitivity D1000 ScreenTape (Agilent Technologies, CA, USA). The

261 library (220 eDNA samples, 27 field blanks, 33 filtration blanks, 17 extraction blanks, 16 PCR

262 negative controls, and 16 PCR positive controls) was sequenced on an Illumina MiSeq® using a

263 MiSeq Reagent Kit v3 (600-cycle) (Illumina, Inc, CA, USA). Raw sequence reads were

264 demultiplexed using a custom Python script. metaBEAT v0.97.11 (https://github.com/HullUni-

265 bioinformatics/metaBEAT) was used for quality trimming, merging, chimera removal, clustering,

266 and taxonomic assignment of sequences against our UK vertebrate reference database (Harper

267 et al., 2018) which contains sequences for 103 UK mammals. Taxonomic assignment used a

268 lowest common ancestor approach based on the top 10% BLAST matches for any query that

269   matched a reference sequence across more than 80% of its length at minimum identity of 98%.

270

271   **2.6 Data analysis**

272

273   Analyses were performed in R v.3.4.3 (R Core Team, 2017). The total unrefined read counts (i.e.

274   raw taxonomically assigned reads) per sample were calculated and retained for downstream

275   analyses. Assignments were corrected: family and genera containing a single UK species were

276   reassigned to that species, species were reassigned to domestic subspecies, and

277   misassignments were corrected, e.g. *Lynx pardinus* and *Lynx lynx*. Manual reassignment

278   duplicated some metaBEAT assignments thus the read count data for these assignments were

279   merged. Taxon-specific sequence thresholds (i.e. maximum sequence frequency of each taxon

280   in PCR positive controls) were used to mitigate cross-contamination and false positives (Table

281   A4, Fig. A3), and remnant contaminants and higher taxonomic assignments removed excluding

282   the following genera. *Anas* (Dabbling ducks) was retained because potential for hybridisation

283   reduced confidence in species-level assignments, and *Emberiza* (Buntings) and *Larus* (White-

284   headed gulls) were retained because reference sequences were missing for several common

285   species. Dataset refinement is fully described in Appendix A. Taxonomic assignments remaining

286   in the refined dataset were predominantly of species resolution and considered true positives.

287   We split the refined dataset by Experiment 1 (artificial waterbodies) and Experiment 2 (natural

288   ponds). Proportional read counts for each species were calculated from the total unrefined

289   read counts per sample. Our proportional read count data were not normally distributed

290   (Shapiro–Wilk normality test: $W = 0.915$, $P < 0.001$), thus we used a Mann-Whitney U test to

291   compare the median proportional read count of stratified and directed samples across species.

292   We employed binomial Generalized Linear Mixed-effects Models (GLMMs) with the logit

293   link function using the package glmmTMB (development version; Brooks et al., 2017) for the

294   following tests. First, we compared the eDNA signals from stratified and directed samples for

295   each mammal species using a hierarchical model including sample type nested within species

296   (fixed) and wildlife park (random) as effects. We tested the influence of species lifestyle on

297   mammal eDNA signals using a model with species lifestyle (fixed) and species nested within

298   wildlife park (random) as effects. Using directed samples, we tested the influence of behaviour

299   on mammal eDNA signals using two hierarchical models, including species nested within

300   wildlife park (random) and specific (e.g. swimming, drinking) or generic (i.e. water contact

301   versus no water contact) behaviour(s) respectively (fixed) as effects. We assessed model fit

302   using diagnostic plots and performed validation checks to ensure model assumptions were met

303   and overdispersion was absent (Zuur, Ieno, Walker, Saveliev, & Smith, 2009).

304   For Experiment 2, we qualitatively compared mammal presence-absence records

305   generated by eDNA metabarcoding, camera trapping, and field signs. TLNR ponds were

306   sampled every 24 hrs for 5 days, thus proportional read counts were averaged across days for

307   comparison to BE and TM ponds (sampled once each). We qualitatively compared the

308   distribution and persistence of eDNA signals between semi-aquatic and terrestrial mammals

309   using tile plots and heat maps of the unaveraged proportional read counts for identified species

310   at TLNR over the 5-day period. All figures were produced using the package ggplot2 v3.0.0

311   (Wickham, 2016).

312

313

3. Results

315

3.1 eDNA metabarcoding

317

The sequencing run generated 47,713,656 raw sequence reads, of which 37,590,828 remained

following trimming, merging, and length filter application. After removal of chimeras and

redundancy via clustering, the library contained 21,127,061 sequences (average read count of

64,215 per sample including controls), of which 16,787,750 (79.46%) were assigned a

taxonomic rank. Contamination (Fig. A4) was observed in the field blanks (badger, beaver, lynx,

pine marten, red squirrel, and water vole) as well as in the filtration and extraction blanks

(human [*Homo sapiens*] and cichlid). PCR negative controls were contaminated to different

extents with human, cichlid, beaver, and pine marten as well as non-focal species. After

threshold application, contaminants remaining in eDNA samples included Gentoo penguin

(*Pygoscelis papua*), reindeer (*Rangifer tarandus*), cichlid, and human. The refined dataset

contained 59 vertebrate species, including six amphibians, 10 fish, 19 birds, and 24 mammals

(Table A5).

330

3.2 Experiment 1: eDNA detection and signal strength in artificial systems

332

All nine focal species were detected in captivity, of which seven were detected in all water

334 samples taken from their respective enclosures. HWP red deer were not detected in 2 of 5

335 stratified samples, and WT hedgehog was not detected in 1 of 2 drinking bowl samples (Fig. 1).

336 'Other' samples (neither directed nor stratified) were excluded from further comparisons, thus

337 hedgehog, red squirrel, and water vole were omitted in downstream analyses. Across species,

338 stratified samples (0.406) had a higher median proportional read count than directed samples

339 (0.373), but this difference was not significant (Mann-Whitney U test: U = 1181.5, P = 0.829).

340 Proportional read counts for directed and stratified samples did not significantly differ (χ^2_6 =

341 0.364, P = 0.999) within species either (Fig. 2a; GLMM: θ = 0.168, χ^2_{53} = 8.915, P = 1.000,

342 pseudo-R^2 = 39.21%). Otter proportional read counts were lower than other species, but not

343 significantly so. Similarly, species lifestyle (semi-aquatic, ground-dwelling, arboreal) did not

344 influence (χ^2_2 = 0.655, P = 0.721) proportional read counts (Fig. 2b; GLMM: θ = 0.213, χ^2_{61} =

345 13.002, P = 1.000, pseudo-R^2 = 11.85%). Proportional read counts did not differ (χ^2_{11} = 1.369, P

346 = 0.999) according to specific behaviours exhibited by species (Fig. 3a; GLMM: θ = 0.355, χ^2_{31} =

347 11.013, P = 0.999, pseudo-R^2 = 9.17%). Likewise, generic behaviour (i.e. water contact versus no

348 water contact) did not influence (χ^2_{11} = 0.002, P = 0.964) proportional read counts (Fig. 3b;

349 GLMM: θ = 0.217, χ^2_{41} = 8.897, P = 1.000, pseudo-R^2 = 8.50%).

350

351 **3.3 Experiment 2: eDNA detection and signal strength in natural systems**

352

353 At natural ponds, eDNA metabarcoding, camera trapping, and field signs all detected beaver,

354 red deer, and roe deer. Camera traps (Fig. 4) and field signs recorded red fox and badger when

355 eDNA metabarcoding did not (Fig. 5). However, eDNA metabarcoding revealed small mammals

356   missed by cameras and field signs, including water vole, water shrew (*Neomys fodiens*), bank

357   vole (*Myodes glareolus*), common shrew (*Sorex araneus*), brown rat (*Rattus norvegicus*), rabbit,

358   grey squirrel, and common pipistrelle (*Pipistrellus pipistrellus*). We observed mice or vole

359   footprints at BE Pond 1, but could not ascertain species. Fig. 5 summarises mammals recorded

360   by different methods at each site with reference to cumulative survey data. Notably, only

361   beaver was found at the same ponds by all methods. Although methods shared species at site

362   level, species were not always detected at the same pond. Detection rates for species captured

363   by at least one survey method are summarised in Table A6.

364   Sampling of natural ponds revealed spatial patterns in eDNA detection and signal

365   strength. eDNA from non-domestic terrestrial mammals (i.e. mammals excluding dog [*Canis*

366   *lupus familiaris*], pig [*Sus scrofa domesticus*], sheep [*Ovis aries*] and cow [*Bos taurus*]) was

367   unevenly dispersed compared with semi-aquatic mammals (Fig. A5). Semi-aquatic beaver and

368   water vole were detected in at least 90% and 60% respectively of water samples (*n* = 10)

369   collected from single ponds, albeit water shrew was only detected in 10% of samples. Non-

370   domestic terrestrial mammals were routinely detected in <20% of water samples collected from

371   a pond and left relatively weak eDNA signals. Overall, beaver was the most consistently

372   detected mammal with the highest proportional read counts. However, the strongest and most

373   evenly distributed signals belonged to amphibians, particularly common frog (*Rana temporaria*)

374   and great crested newt (*Triturus cristatus*) (Fig. A5).

375   TLNR samples collected over a 5-day period (D01-05) revealed that mammal detection

376   heavily depends on the spatial and temporal resolution of eDNA metabarcoding surveys (Fig.

377   A6). Mammal eDNA signals in pond water were ephemeral, often disappearing within 24-48 hrs

378   of initial detection, as opposed to amphibians that were detected for multiple days and whose

379   eDNA signal increased in strength. The majority of semi-aquatic or terrestrial mammals were

380   only detected in a single sample on each day.

381

382

383   ## 4. Discussion

384

385   We have demonstrated the potential of eDNA metabarcoding for monitoring conservation and

386   management priority mammals, but species detection rates are variable. Our experiments have

387   validated this molecular approach and provided new insights that will inform the development

388   and application of mammal eDNA metabarcoding. Sampling strategy, mammal lifestyle, and

389   mammal behaviour did not influence eDNA detection and signal strength in captivity, but all

390   played vital roles in natural ponds. Although semi-aquatic and terrestrial mammals were

391   detected from pond water, their eDNA signals were temporary and weak in comparison to

392   aquatic amphibians and fishes. Nonetheless, this suggests that eDNA is representative of

393   contemporary and local mammal diversity.

394

395   **4.1 Influence of sampling strategy and mammal behaviour on eDNA detection**

396

397   In Experiment 1, all nine focal species were detected in captivity, and seven were detected in all

398   water samples taken from their respective enclosures. This demonstrates that our method can

399   successfully detect a variety of mammals from pond and drinking water. Surprisingly, we found

400   that neither sampling strategy nor mammal lifestyle nor mammal behaviour influenced eDNA

401   detectability and signal strength in captivity. This included behaviours associated with eDNA

402   deposition, e.g. swimming, drinking, urination, and defecation (Rodgers & Mock, 2015; Ushio et

403   al., 2017; Williams et al., 2018). Enclosures were permanently occupied and artificial

404   waterbodies likely saturated with eDNA, which possibly masked behavioural signals. Modest

405   replication may have limited experimental power, preventing patterns being detected

406   statistically. Nonetheless, our results show that mammal contact with water enables eDNA

407   deposition and detection.

408   Unsurprisingly, given the nature of wild mammal interactions with natural systems

409   versus those in captivity, Experiment 2 results highlight the challenges of mammal eDNA

410   detection. We recorded 17 mammals using three monitoring tools, comparable to the 17

411   mammals expected from cumulative survey data despite discordance. Field signs and camera

412   trapping detected red fox and badger where eDNA metabarcoding did not, but eDNA

413   metabarcoding identified water vole and other small mammals missed on camera or with

414   ambiguous field signs, i.e. mice, voles, shrews. Importantly, camera trap deployment period,

415   height, and positioning may have influenced small mammal detection by this method

416   (Caravaggi et al., 2018). Ishige et al. (2017) achieved comparable mammal detection at salt licks

417   with eDNA metabarcoding and camera trapping, but species presence was inconsistent

418   between salt licks surveyed. Using multi-species occupancy modelling for three mammal

419   species, Sales et al. (2019) observed water-based eDNA metabarcoding provided comparable

420   detection probabilities to conventional survey methods and actually outperformed camera

421   trapping. Similarly, Leempoel et al. (2019) found soil-based eDNA metabarcoding identified the

422 same mammals as camera trapping as well as small mammals rarely seen on camera, albeit the

423 methods differed between sites. Our own results echo all three studies, where despite some

424 inconsistencies, eDNA metabarcoding enhanced species inventories and identified smaller,

425 cryptic taxa.

426 Notably, no survey method captured semi-aquatic otter despite presence at study sites

427 and successful detection in eDNA metabarcoding studies of UK ponds (Harper et al., 2019),

428 lakes (Hänfling et al., 2017), and rivers/streams (Sales et al., 2019). Captive otter also had a

429 weaker eDNA signal than other semi-aquatic mammals studied here. Lower eDNA detection

430 rates for otter, badger, and red fox may stem from species' ecologies (Sales et al., 2019). These

431 mammals are wide-ranging (Gaughran et al., 2018; Thomsen et al., 2012) and may not readily

432 release DNA in water. Otters often spraint on grass or rock substrata outside water and use

433 latrines associated with caves and dens (Ruiz-Olmo & Gosálbez, 1997). As terrestrial mammals,

434 red fox and badger must drink from or enter ponds for eDNA deposition to occur (Rodgers &

435 Mock, 2015; Ushio et al., 2017; Williams et al., 2018). Otter, badger, and red fox detection may

436 require greater spatiotemporal resolution of eDNA sampling. This is reinforced by other eDNA

437 metabarcoding studies where mammal detection was highly variable across sites surveyed

438 (Ishige et al., 2017; Klymus et al., 2017; Leempoel et al., 2019; Sales et al., 2019; Ushio et al.,

439 2017). False negatives may instead be symptomatic of metabarcoding bias, but this is unlikely in

440 our study (section 4.2).

441 eDNA from other semi-aquatic mammals was evenly distributed, being found in most or

442 all samples collected on fine spatial scales within natural ponds, whereas terrestrial mammal

443 eDNA was highly localised and detected in few (<20%) samples. Mammal eDNA signals varied

444   temporally, being detectable for two consecutive days maximum. Depending on the species,

445   mammal eDNA may be spatially and temporally clumped in lentic ecosystems due to the nature

446   and frequency of water contact. Unless non-domestic mammals exhibit behaviours involving

447   prolonged water contact (e.g. swimming, wallowing), they may only be detected at drinking

448   sites (Klymus et al., 2017; Ushio et al., 2017; Williams et al., 2018). Conversely, domestic

449   mammals may have elevated detection rates in ponds due to high occurrence of these

450   waterbodies in agricultural landscapes as well as eDNA transport by rainfall and run-off (Staley

451   et al., 2018). eDNA detection and persistence are further influenced by group size, where eDNA

452   from multiple individuals endures for longer periods in water than eDNA from single individuals

453   (Williams et al., 2018). Detailed investigations incorporating biotic (e.g. population size, body

454   mass, behaviour) and abiotic (e.g. temperature, pH, rainfall) factors are needed to understand

455   the longevity of mammal eDNA signals in aquatic ecosystems (Rodgers & Mock, 2015; Sales et

456   al., 2019; Williams et al., 2018).

457   Our two experiments have shown that sampling strategy influences mammal eDNA

458   detection. Mammal eDNA was evenly distributed in closed, artificial waterbodies, but locally

459   distributed in open, natural ponds. Captive mammal enclosures contained one species

460   (excluding HWP red deer) and a drinking container(s) and/or small waterbody (range 0.01-162

461   m^2, mean 27.4 m^2). Some enclosures housed more individuals of a species than others, thereby

462   increasing eDNA deposition and detection probability (Williams et al., 2018). Wild mammals

463   have an array of freshwater habitats at their disposal and can hold vast territories. Therefore,

464   rates of pond visitation and eDNA deposition are more irregular (Klymus et al., 2017; Ushio et

465   al., 2017), possibly leading to between-sample variation (Williams et al., 2018).

466

4.2 Accounting for false positives and false negatives in metabarcoding

468

eDNA metabarcoding has potential for inclusion in mammal monitoring schemes (section 4.3), but like existing monitoring tools, may produce false negatives or false positives. Our process controls identified low-level contamination at all stages of metabarcoding, but primarily during sampling or PCR (Appendix A). We applied taxon-specific sequence thresholds to our data to mitigate false positives as in Harper et al. (2019). Remnant contaminants were cichlid (laboratory), Gentoo penguin (environment), reindeer (environment), and human (environment/laboratory). Gentoo penguin is housed at EZ and was identified from EZ beaver enclosure water. The WT red squirrel and reindeer enclosures are in close proximity. DNA transport by wildlife (e.g. waterfowl [Hänfling et al., 2016]) and park staff/visitors may explain this environmental contamination. Human DNA was present across process controls corresponding to artificial and natural waterbodies. Human DNA may be amplified and sequenced instead of focal species, potentially resulting in false negative detections for rare and/or less abundant species. Human DNA blocking primers can prevent this bias, but may impair PCR amplification efficiency (Klymus et al., 2017; Ushio et al., 2017; Valentini et al., 2016). Sequence thresholds are one method of accounting for contamination in metabarcoding datasets, but this is a topic that warrants deeper investigation aimed at researching and refining standardised methods for false positive identification and mitigation, e.g. the R package microDecon (McKnight et al., 2019).

In our study, eDNA metabarcoding produced false negatives for otter, badger, and red

488   fox at natural ponds. We selected a 12S metabarcode designed to amplify vertebrate DNA (Riaz

489   et al., 2011). One of four fox reference sequences (NCBI Accession: KF387633.1) possessed one

490   mismatch to the forward primer, and one of three otter reference sequences (NCBI Accession:

491   EF672696.1) possessed one mismatch to the reverse primer. These mismatches did not occur

492   within the first or last four bases of either primer sequence, and there were no primer

493   mismatches with the badger reference sequences (Harper et al., 2018). Therefore, amplification

494   bias was not responsible for these false negatives. DNA from aquatic and more abundant

495   species may have overwhelmed otter, badger, and red fox DNA during amplification and

496   sequencing, i.e. species-masking (Kelly, Port, Yamahara, & Crowder, 2014; Klymus et al., 2017).

497   Species-masking may also arise from use of proportional read counts as an index of eDNA signal

498   strength. High proportional read counts for a species may translate to a weak eDNA signal if the

499   total mammalian eDNA concentration is highly variable between samples or lower than the

500   total eDNA concentration for other taxonomic groups in a sample. Metabarcoding primers

501   targeting mammals (Ushio et al., 2017) or multi-marker (e.g. 12S, 16S, COI) investigations

502   (Evans et al., 2017; Hänfling et al., 2016; Kelly et al., 2014; Klymus et al., 2017) may improve

503   mammal detection in systems with competition from non-target aquatic species and where

504   total mammalian eDNA concentration varies between samples. Similarly, more biological and

505   technical replication may improve species detection probabilities (Evans et al., 2017; Lawson

506   Handley et al., 2019; Sales et al., 2019; Valentini et al., 2016). Importantly, otter also had lower

507   qPCR detection than amphibians and fish (Thomsen et al., 2012). A metabarcoding and qPCR

508   comparison (e.g. Harper et al., 2018; Lacoursière-Roussel, Dubois, Normandeau, & Bernatchez,

509   2016) would confirm whether poor amplification efficiency for otter arises from technical bias

510 or species ecology, and whether eDNA metabarcoding can reliably monitor otter alongside the

511 wider mammalian community.

512

513 **4.3 Scope of eDNA metabarcoding for mammal monitoring**

514

515 Mammal population assessments are hindered by lack of data and systematic monitoring for

516 many species (Mathews et al., 2018). Distribution and occupancy data are poor for most

517 species, with ongoing survey effort biased toward rare species. Surveys heavily rely on citizen

518 science and casual records (Massimino et al., 2018). Tools that provide standardised, systematic

519 monitoring of mammal populations are needed (Mathews et al., 2018). Despite issues inherent

520 to metabarcoding for biodiversity monitoring (Deiner et al., 2017), this tool has enormous

521 potential to enhance mammal monitoring, conservation, and management. eDNA

522 metabarcoding generates distribution data for multiple species, whether rare, invasive, or

523 abundant, and could track conflicting species simultaneously, e.g. water vole, American mink,

524 and otter (Bonesi & Macdonald, 2004) or red squirrel, grey squirrel, and pine marten (Sheehy,

525 Sutherland, O'Reilly, & Lambin, 2018).

526 eDNA metabarcoding can rapidly survey multitudes of aquatic sites at landscape-scale

527 where camera traps might be resource-intensive, cost-inefficient, and susceptible to

528 theft/damage (Ushio et al., 2017). Field signs require volunteer time and skill (Sadlier et al.,

529 2004) to be employed at comparable spatial scales to eDNA metabarcoding which could

530 provide accurate data for species misidentified from field signs, e.g. mice and voles, otter and

531 mink (Franklin et al., 2019; Harris & Yalden, 2004). However, camera traps and field signs both

532   recorded species that eDNA metabarcoding missed. Therefore, eDNA metabarcoding is

533   complementary and should be incorporated into, not replace, existing monitoring schemes

534   (Leempoel et al., 2019; Sales et al., 2019). This tool could be most effective in mammal

535   monitoring if deployed at the edges of known species distributions, in areas where species

536   presence is unknown, and in areas with isolated species records (Mathews et al., 2018).

537

538   **4.4 Recommendations for mammal survey using eDNA metabarcoding**

539

540   Water-based eDNA metabarcoding shows great promise for mammal monitoring encompassing

541   conservation and management priority species (Sales et al., 2019). However, there are factors

542   to be considered when designing and conducting mammal eDNA surveys that may not be

543   problematic for surveys of fishes or amphibians. Mammal eDNA detection probabilities from

544   natural ponds will likely be high when areas with dense populations are studied, but rigorous

545   sampling strategies will be required to track mammals in areas sparsely populated by

546   individuals. Multiple ponds must be sampled repeatedly, and samples taken at multiple

547   locations within ponds without pooling to enable site occupancy inferences. Importantly, we

548   sampled natural ponds in spring but sampling in other seasons may produce different results,

549   reflective of species' ecologies (Lawson Handley et al., 2019). To account for differential

550   mammal visitation rates and maximise eDNA detection probabilities, we recommend that

551   researchers and practitioners using eDNA metabarcoding for mammal monitoring channel their

552   efforts into extensive sampling of numerous waterbodies in a given area over prolonged

553   timescales. Water-based eDNA appears to be indicative of contemporary mammal presence,

554   with most mammal eDNA signals lost within 1-2 days. Therefore, eDNA metabarcoding could

555   provide valuable mammalian community "snapshots" that may not be obtained with other

556   survey methods (Ushio et al., 2017). Different sample types (e.g. water, soil, snow, salt licks,

557   feeding traces, faeces, hair, and blood meals) may also offer new insights to mammal

558   biodiversity (Franklin et al., 2019; Ishige et al., 2017; Kinoshita et al., 2019; Leempoel et al.,

559   2019; Sales et al., 2019; Tessler et al., 2018; Ushio et al., 2017).

560

561

562   **Data accessibility**

563

564   Raw sequence reads have been archived on the NCBI Sequence Read Archive (Study:

565   SRP164740; BioProject: PRJNA495011; BioSamples: SAMN10195928 - SAMN10196255; SRA

566   accessions: SRR7986451 - SRR7986778). Jupyter notebooks, R scripts and corresponding data

567   are archived online (https://doi.org/10.5281/zenodo.2561415).

568

584

Author contributions

586

587 L.R.H, B.H, and L.L.H conceived and designed the study. A.I.C and M.G coordinated sampling at

588 Wildwood Trust and RZSS Highland Wildlife Park respectively. L.R.H, C.D.M, C.J.M, and T.L

589 collected and filtered water samples. A.L, T.L, and T.B helped select natural ponds to be

590 surveyed using eDNA, camera trapping, and field signs, and provided camera traps for the

591 study. L.R.H, A.L, and T.L deployed camera traps, which were then collected and footage

592 analysed by L.R.H. L.R.H processed samples in the laboratory with advice from C.D.M and A.M.

593 D.S.R sequenced the final library. L.R.H completed bioinformatic processing of samples, and

594 subsequent data analysis. L.R.H wrote the manuscript, which all authors contributed critically to

595 drafts of and gave final approval for publication.

758

759 **Table 1.** Ethogram used to catalogue mammal behaviours that occur in or near artificial

760 waterbodies in captive enclosures. Importantly, this ethogram was designed to catalogue

761 mammal behaviours potentially leading to eDNA deposition. Therefore, it may not be

762 comparable to ethograms typically used in study of captive animals.

763

| Behaviour	Definition
Swimming	Mammal completely submerged in and moving through waterbody using limbs
Bodypart in water	Mammal partially submerged in waterbody, e.g. foot or tail in water
Drinking	Water taken into mouth and swallowed by mammal
Feeding	Food taken into mouth and swallowed by mammal in or near waterbody, e.g. otter and fish
Scratching	Bodypart or external object in enclosure used by mammal to relieve itch near waterbody
Urinating/scent-marking	Liquid excretion passed by mammal in or near waterbody
Pooing	Solid excretion passed by mammal in or near waterbody
Sniffing	Air visibly drawn through nose of mammal to detect a smell around waterbody, possibly involving contact with water
Standing	Mammal motionless in or near waterbody
Walking	Mammal moving around waterbody at a regular pace by lifting and setting down each foot in turn, never having both feet off the ground at once
Running	Mammal moving around waterbody at a speed faster than a walk, never having both or all the feet on the ground at the same time
Vocalising	Mammal producing sound while in or near waterbody
Grooming	Mammal cleaning fur or skin with its tongue while in or near waterbody
Resting	Mammal lying down or sitting in or near waterbody
Other	Behaviour exhibited in or near waterbody that does not conform to other categories, e.g. chasing tail
Not visible	Mammal moved to part of enclosure not visible to the observer

764

765 **Table 2.** Summary of focal species studied at wildlife parks and their lifestyle. The number of

766 individuals present and waterbody size in enclosures is provided.

767

Site	Species	Lifestyle	Enclosure	Number of individuals	Waterbody size (m^2)
Wildwood Trust	European otter (*Lutra lutra*)	Semi-aquatic	1	2	162
	European water vole (*Arvicola amphibius*)	Semi-aquatic	1	4	0.09
			2	1	0.09
	European beaver (*Castor fiber*)	Semi-aquatic	1	2	100
			2	1	100
	European hedgehog (*Erinaceus europaeus*)	Ground-dwelling	1	1	0.04
			2	2	0.04
	European badger (*Meles meles*)	Ground-dwelling	1	4	1.73
	Red deer (*Cervus elaphus*)	Ground-dwelling	1	8	100
	Eurasian lynx (*Lynx lynx*)	Ground-dwelling	1	2	2
	Red squirrel (*Sciurus vulgaris*)	Arboreal	1	2	0.01
			2	3	0.01
			3	3	0.01
			4	2	0.01
	European pine marten (*Martes martes*)	Arboreal	1	1	2
			2	1	0.375
Highland Wildlife Park	Red squirrel (*Sciurus vulgaris*)	Arboreal	NA	NA	0.25
	Eurasian lynx (*Lynx lynx*)	Ground-dwelling	1	8	2
	European beaver (*Castor fiber*)	Semi-aquatic	1	2	50
	Red deer (*Cervus elaphus*)	Ground-dwelling	1	30	NA

768

769
Figure 1. Heatmap showing proportional read counts for eDNA samples (n = 81) from Experiment 1. The heatmap is faceted by sample type (directed, stratified or other) and wildlife park (Highland Wildlife Park or Wildwood Trust). Each cell represents an individual sample taken from an enclosure containing the focal species in that row. Directed (DIR01-DIR06) and stratified (STR01-STR06) samples were collected for each species from artificial waterbodies. Samples were also collected from drinking containers (E1, E2, E3, E4, BOWL, BUCK), water vole (QUAR1, QUAR2) and RZSS Edinburgh Zoo beaver (ZOO) enclosures, and a water bath (BATH) in RZSS Highland Wildlife Park woods. The maximum proportional read count for each cell (i.e. sample) is 1, if all reads from a particular sample belonged to the focal species. Cells containing 0 represent samples with proportional read counts less than 0.01 whereas empty cells are samples with proportional read counts of exactly 0.
Figure 2. Relationships predicted by the binomial GLMMs between proportional read counts and sample type nested within species **(a)** or species lifestyle **(b)** for Experiment 1. The observed data (coloured points) are displayed against the predicted relationships (black points with error bars) for each species **(a)** or species lifestyle **(b)**. Points are shaped by sample type **(a)** or wildlife park **(b)**, and coloured by species lifestyle. Error bars represent the standard error around the predicted means.

**Figure 3.** Boxplots showing the mean proportional read counts for specific **(a)** and generic **(b)** behaviour(s) exhibited by focal species in Experiment 1. Boxes show 25th, 50th, and 75th percentiles, and whiskers show 5th and 95th percentiles. Points are coloured by species lifestyle, and each point in **(a)** represents a directed sample sized by frequency of behaviour. The behaviour 'none' for beaver represents occurrences of beaver in water but out of view of camera traps.
Figure 4. Exemplar camera trap photos taken at natural ponds where focal species were present in Experiment 2. Red deer was recorded at Thorne Moors **(a)**, roe deer **(b)** and red fox **(c)** were recorded at Tophill Low Nature Reserve, and beaver was recorded at the Bamff Estate **(d)**.

Figure 5. Tile plot showing species presence-absence at individual pond and site-level as indicated by field signs, camera trapping, and eDNA metabarcoding in Experiment 2. Surveys were performed at sites where focal species presence was confirmed by cumulative survey data.
