Role of symptom recognition in help-seeking for RA

Symptom recognition and perceived urgency of help-seeking for members of the symptoms of general public for rheumatoid arthritis, compared with other common diseases: a mixed method approach

Role of symptom recognition in help-seeking for RA

Abstract

Objective: Clinical outcomes in Rheumatoid arthritis (RA) requires treatment in its earliest stages in order to reduce the risk of joint damage and disability. Disease is treated early. However, the therapeutic window is often missed as a result of delayed help seeking by patients who fail to recognise its symptoms or the need for rapid medical attention. We conducted two studies to investigate the role of symptom recognition in help-seeking for the symptoms of RA, and compared this with angina and bowel cancer.

Methods: We conducted a qualitative interview study with 31 individuals and a postal survey of 1088 members of the general public (all without RA). Both studies used vignettes describing the symptoms of RA, bowel cancer and angina. Participants made causal attributions and rated the perceived seriousness of the symptoms and the urgency with which they would seek medical help if confronted with these symptoms.

Results: Only a small proportion of participants in both studies recognised the symptoms of RA, whereas the symptoms of bowel cancer and angina were readily recognised by many participants and considered to be more serious and to require more rapid medical attention (Z values of 14.7 to 34.2, p < .001).

Conclusion: Accurate symptom attribution and the perception that symptoms are indicative of a serious underlying condition are both important drivers for rapid help seeking. In the case of angina and bowel cancer, recent campaigns have promoted not only recognition of symptoms and their seriousness, but also emphasised the consequences of not seeking timely help. Our results suggest that these consequences should also be addressed in any public health campaign for RA.
Role of symptom recognition in help-seeking for RA

Significance and Innovations

- Members of the general public in the UK were less likely to make an accurate causal attribution for the symptoms of RA compared to the symptoms of bowel cancer or angina. The general public further perceived RA to be less serious and less urgent than other conditions.
- Correct causal attribution had a positive impact on the urgency with which people intended to seek medical attention.
- The findings highlight a need to raise public awareness not only about the symptoms of RA but also the need for prompt treatment, and thus the importance of early help-seeking.
Role of symptom recognition in help-seeking for RA

Rheumatoid arthritis (RA) is a chronic inflammatory disease with a prevalence of approximately 1.16% in women and 0.44% in men(1). Early treatment reduces the risk of permanent joint damage and disability(2-7), however, the commencement of disease modifying therapy is often delayed and the therapeutic window missed(5;8-11). One important source of delay is the patient themselves who often wait many weeks before seeking medical attention for their symptoms(11).

When a person experiences symptoms they usually need to infer illness or an external cause (e.g. injury) before seeking medical attention a causal disease for which therapy may be available(12-14). The appraisal of symptoms and subsequent decision-making are influenced by a range of demographic, socio-cultural and psychological factors(15;16) including the knowledge and beliefs that an individual has about a disease(17).

In the case of familiar or well-publicised illnesses such as flu correct causal attribution is relatively straightforward; however, for less well-known illnesses, such as RA, this may be more challenging. It has previously been shown that people often misinterpret the symptoms of RA(18), for example confusing them with those of osteoarthritis or interpreting them as a natural consequence of ageing(17). Lack of awareness of the symptoms of RA, its consequences and the availability of effective disease modifying therapies are possible explanations for patient delay following the onset of RA symptoms.

Public health campaigns can have a positive impact on symptom recognition and subsequent decisions about seeking medical attention. For example, one ‘Be Clear
Role of symptom recognition in help-seeking for RA on Cancer’ (BCOC; Public Health England) campaign targeted bowel cancer via TV and radio advertisements, and posters on public transport and in doctor’ surgeries(19), resulting in increased knowledge and more rapid help seeking(20;21). Other recent public health campaigns in the UK include initiatives to raise awareness of ischaemic heart disease(22). In contrast efforts to increase public awareness of RA symptoms have been limited in the UK(23).

Due to the recent public awareness campaigns for bowel cancer and ischaemic heart disease, we expect that people are more aware of the symptoms of these conditions than those of RA, and that they are more likely to attribute these symptoms to the correct illness, and to seek early and appropriate medical help. This paper describes two studies designed to assess the role of disease knowledge and symptom recognition in decision-making about help-seeking in RA compared with these other two diseases.

PARTICIPANTS AND METHODS
Data derive from a qualitative interview study and a quantitative postal survey, both involving members of the general public without inflammatory arthritis. The studies compared symptom recognition for RA with that for bowel cancer and angina and explored the effect of correct causal attribution and perceived level of seriousness of the symptoms on the urgency with which people would intended to seek medical help for each of these conditions.

Qualitative study: data collection and analysis
Role of symptom recognition in help-seeking for RA

Patients registered at two inner city general practices, aged 18 years and over, without a diagnosis of inflammatory arthritis were sent postal invitations to participate. Participants were purposively sampled from three age groups (18-40, 41-60 and over 61 years) to reflect the age distribution for RA onset (24). The study was also advertised using posters at the Universities of Birmingham and Keele.

32 individuals were recruited (31 by post and 1 through poster advertisement). One participant’s data, collected during the only telephone interview conducted during the study, were discarded due to technical problems with the recording. The remaining 31 participants (16 females) were aged between 23 and 84 years and all but two were of a white ethnic background (Supplementary Table 2 for further demographic information).

The semi-structured interviews were conducted face-to-face (by GS) in the general practices, at the University of Birmingham or via the telephone. Interviews lasted approximately 60 minutes and were guided by an interview schedule developed in collaboration with patient research partners and informed by previous research (17;18). Participants were asked to read and discuss two written vignettes describing what a person with common symptoms of early RA would experience (a: ‘Joint pain and stiffness in hands and wrists’ and b: ‘Joint pain, stiffness and swelling in hands and wrists’), a vignette describing bowel cancer symptoms and a vignette describing the symptoms of angina (Supplementary Table 1). The order of the vignettes was alternated between interviewees with either the RA vignettes or the bowel cancer and angina vignettes discussed first. Interview questions explored participants’ perceptions of the symptoms, including the seriousness of the
Role of symptom recognition in help-seeking for RA symptoms, and participants’ anticipated courses of action if they were to experience such symptoms.

Interviews were audio recorded, and transcribed verbatim. Blind coding of five of the transcripts was undertaken by KK and GS. A few minor discrepancies in coding were discussed and resolved before the full coding was undertaken by GS using qualitative data analysis software package NVivo, version 10 (QSR International). GS organised the coded data into themes based on the most frequently occurring and noteworthy emergent themes. Thematic analysis was used to inform the analytic procedure (25). Data presented in this manuscript focus on themes related to possible causes of symptoms, their perceived seriousness, and likely help-seeking after their development.

Quantitative study: data collection and analysis

The postal survey was mailed to a cohort of 3400 persons registered with one of four inner-city general practices, who were over 18 years of age, and without a diagnosis of inflammatory arthritis. 1088 people (291 males, 788 females; 9 did not answer the gender question) aged between 18 and 96 years completed the survey (response rate 32%). The majority (84.5%) of participants were of a white ethnic background (Supplementary Table 3 for further demographic information).

The self-completion questionnaires included five vignettes, similar to those used in the qualitative interviews, describing symptoms of; a) RA: joint pain and stiffness in hands and wrists; b) RA: joint pain, stiffness and swelling in hands and wrists; c) RA: joint pain, stiffness and swelling in feet and ankles; d) bowel cancer; and e)
Role of symptom recognition in help-seeking for RA

angina. The order of these vignettes was fixed in the survey. For each vignette, respondents were asked to rate the seriousness of the symptoms and how quickly they would seek medical help for the symptoms (urgency) using 5-point Likert scales ranging from 1 (Very) to 5 (Not at all).

Respondents were also asked to describe what they thought might have caused the symptoms. These open ended answers were coded according to diagnosis by one coder and checked for accuracy by a second coder. Any discrepancies were discussed and resolved. These codes were subsequently classified as 'correct' (when the cause was identified correctly, e.g. RA, angina/ischaemic heart disease or bowel cancer); 'approximate' (when the given cause approximated the correct one, e.g. ‘arthritis’ instead of RA or ‘cancer’ instead of bowel cancer) and ‘incorrect’ (when either an incorrect cause was given for example ‘water retention’ or when the participant indicated that they did not know the answer or left the question blank).

Coded causal attributions were described using percentage distributions and ratings were described using median values and interquartile ranges. Within group comparisons between conditions on the ratings for urgency and seriousness were conducted using nonparametric Friedman tests. Urgency ratings of those respondents who made a correct causal attribution were compared with those who made approximate and incorrect ones using a Kruskal-Wallis test. For both tests built-in post hoc pairwise multiple comparisons were undertaken based on Dunn's approach with Bonferroni correction(26). Standardised z-values are reported with adjusted p-values. Spearman rank-order correlations were used to describe the relationship between the ratings of seriousness and urgency for each vignette.
Role of symptom recognition in help-seeking for RA

RESULTS

Symptom recognition: cause of the symptoms

In both studies participants were asked to assign a possible cause for the symptoms presented in the vignettes. Illustrative Percentages of survey respondents giving correct, approximate and incorrect causes for each of the vignettes and illustrative interview quotes referred to in the text can be found in Table 1 and (further illustrative quotes can be found in Supplementary Table 4).

RA vignettes. In response to reading vignette Vignette a (joint pain and stiffness in hands and wrists), interviewees often described ‘arthritis’, ‘old age’ and or ‘wear and tear’ as the likely cause of these symptoms, but were unable to specify a particular type of arthritis (Table 1, Quote 1 (T1Q12 T1Q2) and T1Q2T1Q3). Frequently, interviewees would respond ‘I have got that’, apparently attributing these symptoms to other forms of arthritis, such as OA, or other causes of musculoskeletal symptoms which they themselves suffered from. Some interviewees did mention RA spontaneously (T1Q3T1Q1). Others correctly indicated that the symptoms were related to an ‘autoimmune type of arthritis’, although this type of association was mainly made by interviewees with a medical background (see Supplementary Table 1).

For some interviewees, the inclusion of swelling alongside joint pain and stiffness (Vignette b) changed their perception of the possible underlying diagnosis or made them uncertain of the cause (T1Q4T1Q5). Others saw the addition of swelling as reflecting a progression of the (rheumatoid) arthritis they had previously identified. In some cases, interviewees’ perceptions of the underlying diagnosis would change as a result of the location of the symptoms, for example when the interviewer described...
Role of symptom recognition in help-seeking for RA

the symptoms as occurring in the 'feet and ankles' instead some participants
changed their causal attribution from 'arthritis' to 'water retention'. Others recognized
(T1Q4). Several interviewees freely admitted that the symptoms of many arthritides
could occur in a wide range of joints, although many still failed to recognize that
these were the symptoms of RA, they struggled to identify the cause (T1Q6).

The percentages of survey respondents making correct, approximate, or incorrect
causal attributions for each vignette are described in Table 2. Only 14% ofWhen the
interviewer described the symptoms as occurring in the 'feet and ankles', several
interviewees recognized that the symptoms of many arthritides could occur in a wide
range of joints (T1Q8) and mentioned that the cause of the symptoms was the same
for both scenarios (T1Q7) although many still failed to recognize that these were the
symptoms of RA.

Only 14% of survey respondents mentioned RA in response to 'joint stiffness and
pain in hands and wrists', 15% mentioned RA when 'joint swelling' was added, and
11% recognised the symptoms as those of RA when they occurred in the 'feet and
ankles' rather than in the 'hands and wrists'. (see also table 1). Large proportions of
respondents approximately identified the cause by mentioning 'arthritis' including
specific types of arthritis such as gout and OA or 'inflammation': 48% for 'joint
stiffness and pain in hands and wrists', 35% when 'joint swelling' was also included
and 33% for symptoms in 'feet and ankles'. The remaining respondents did not
correctly identify the cause of the symptoms or gave no cause. Incorrect causal
attributions included old age, wear and tear, injury, lack of exercise, inappropriate
exercise and water retention.
Role of symptom recognition in help-seeking for RA

**Bowel cancer vignette.** Although a few interviewees attributed the cause of bowel cancer symptoms to a minor ailment, such as a ‘stomach bug’ (T1Q5T1Q13), most interviewees identified the cause of these symptoms as bowel cancer, frequently accompanied by a list of other possible underlying conditions, such as ‘piles’ and ‘tummy upsets’ (T1Q6, T1Q10) or cancer in general (T1Q12). Several interviewees indicated that they had heard about the symptoms of bowel cancer through the BCOC campaign (19) which had helped them recognise the cause of the symptoms described, their seriousness and the need for rapid help-seeking (T1Q7, T1Q11). Even those who did not specifically name bowel cancer as a cause of the symptoms often mentioned that they knew urgent help was needed as a result of such a campaign. Others mentioned having been invited to send away a stool sample for testing as part of the public health campaign (see Supplementary Table 4).

Similarly, 47% of survey respondents correctly identified bowel cancer (Table 21), 18% approximately identified the cause (i.e. mentioned cancer or Crohn’s disease) and the remaining respondents either did not identify a cause or gave an incorrect cause such as haemorrhoids.

**Angina vignette.** Although the symptoms of angina were often recognised by the interviewees as related to ‘the heart’ or a ‘heart attack’ (T1Q15), fewer interviewees spontaneously labelled them as the symptoms of angina or ischaemic heart disease (T1Q8, T1Q14). Some interviewees indicated that the severity of the angina symptoms (i.e. the degree of pain/ tightness across the chest) would determine the perceived identity of the illness (i.e. whether they were due to angina or a
Role of symptom recognition in help-seeking for RA myocardial infarction). A few interviewees suggested an underlying diagnosis unrelated to heart disease such as asthma (T1Q9T1Q16).

32% of survey respondents correctly identified the symptoms as angina or heart attack, another 32% approximately identified the cause, and the remaining respondents either gave no cause or an incorrect cause such as asthma or anxiety (Table 2).

Symptom recognition: Seriousness of the symptoms

Illustrative quotes referred to in the text can be found in Table 2 and further illustrative quotes can be found in Supplementary Table 4.

RA vignettes. How serious the symptoms of RA were perceived to be by the interviewees varied considerably and was often dependent on the causal attribution (i.e. some types of arthritis were considered to be more serious than others). Some felt that joint pain and stiffness was more serious if experienced in younger people (T1Q10, Table 2, Quote 1; T2Q1). Others did not think the symptoms were serious and would intended to only take action if symptoms worsened (T4T1T2Q2). Many saw the combination of ‘joint pain, swelling and stiffness’ as more serious than just ‘joint pain and stiffness’. A sudden onset of symptoms (as opposed to an insidious onset) and having swelling, pain and stiffness in multiple joints (as opposed to a single joint) were identified as factors indicative of a more serious underlying diagnosis.
Role of symptom recognition in help-seeking for RA

**Bowel cancer vignette.** Interviewees often referred to the occurrence of blood in their stool as a serious symptom (T1Q12T2Q3). Perceived seriousness was increased if these symptoms occurred on multiple occasions (T1Q13T2Q4).

**Angina vignette.** Most interviewees saw the symptoms of angina as being serious and requiring urgent action (T1Q14T2Q5). Again, perceived seriousness was also associated with the frequency with which symptoms occurred.

**Comparison of seriousness ratings across conditions.** Figure 1 illustrates how survey respondents rated the seriousness of each symptom vignette (From ‘not serious at all’ to ‘very serious’). There was a significant difference between rankings for the various vignettes ($\chi^2 = 2034, p < 0.001$). Post hoc comparisons showed that respondents rated bowel cancer and angina symptoms to be significantly more serious than any of the three combinations of RA symptoms ($Z$ values of 16.3 to 25.3, all $p<.001$). They also rated the RA vignette with ‘joint pain and stiffness in hands and wrists’ as significantly less serious than either ‘joint pain, stiffness and swelling in hands and wrists’ ($Z = 9.02, p<.001$) or symptoms in the ‘feet and ankles’ ($Z = 7.75, p<.001$). Ratings for the latter two vignettes (hands vs feet) did not differ significantly ($Z = 1.27, p=1.00$). Table 3 gives descriptive statistics for seriousness ratings for each vignette.

**Perceived urgency of help-seeking**

Illustrative quotes referred to in the text can be found in Table 2 and further illustrative quotes can be found in Supplementary Table 4.
Role of symptom recognition in help-seeking for RA

**RA vignettes.** The symptoms of RA described in the vignettes were generally not seen as urgent, and many interviewees indicated that their intention would be to wait for time periods ranging from a few weeks to several months before seeking medical attention. Some interviewees felt that they *could* be able to live with the symptoms and medical attention was not necessary at all (T1Q15 T2Q6). When swelling was included in the vignette, or when symptoms occurred in multiple joints some interviewees indicated that their intention would be to seek help more urgently (T1Q16 T2Q7). Others felt that in certain circumstances, for example when there was a sudden onset of symptoms, their intention would be to seek help immediately, perhaps even making an emergency appointment at their doctors or going to the emergency room.

**Bowel cancer vignette.** Most interviewees felt that the symptoms of bowel cancer warranted a visit to the family practitioner within a few days of symptom onset, whereas some felt they *should* see their doctor immediately if they experienced these symptoms (T2Q8). However, none felt that emergency medical attention would be necessary (T1Q17). Interviewees generally *felt* that they would not wait for weight loss to occur, or let the symptoms persist for a month (as the text in the vignette suggested) before seeking help (T1Q18 T2Q9).

**Angina vignette.** Interviewees reported that they *would* seek help urgently for the symptoms of angina, and several interviewees would consider contacting the emergency services. Many indicated that their actions would depend on the severity of the symptoms (T1Q19 T2Q10). Some people *reported* that they...
Role of symptom recognition in help-seeking for RA

would live with the symptoms for longer if they felt that as long as the frequency of the attacks or severity of the symptoms would allow them to do so (T1Q20 T2Q11).

Comparison across vignettes of survey urgency ratings. Several interviewees spontaneously indicated that they would report the intention to wait for far longer with the symptoms of RA compared to those of either angina or bowel cancer before seeking medical attention (T1Q21 T2Q12). The differences between conditions found in the interviews are in agreement with the survey results. Figure 2 illustrates the distribution of respondents' ratings of how quickly they would seek help for each vignette. A significant difference among the ratings for the 5 vignettes was found ($\chi^2 = 2106$, $p < .001$). Survey respondents would seek medical attention significantly more quickly for bowel cancer and angina symptoms than they would for any of the given combinations of RA symptoms (Z values of 14.7 to 34.2, all $p < .001$).

Respondents rated 'joint pain and stiffness in hands and wrists' as significantly less urgent compared to either 'joint pain, stiffness and swelling in hands and wrists' ($Z = 9.3$, $p < .001$,) or symptoms in the 'feet and ankles' ($Z = 12.5$, $p < .001$). Ratings of the latter two vignettes (hands and wrists vs feet and ankles) also differed significantly ($Z = 3.2$, $p < .05$) (see Table 3 for descriptive statistics).

Impact of correct causal attribution on the urgency with which help would be sought

Symptom recognition had a significant impact on the urgency with which survey respondents would intended to seek help (Table 4). For all vignettes except for the RA one with symptoms in the 'ankles and feet', having correct knowledge of the cause of symptoms was associated with significantly higher ratings of perceived
Role of symptom recognition in help-seeking for RA

urgency compared to incorrect causal attributions. For all vignettes, except for RA with 'joint pain, stiffness and swelling in the hands and wrists' and RA with symptoms in the ankles and feet', having approximate knowledge of the cause was also associated with significantly higher ratings of perceived urgency compared to incorrect causal attributions. These differences where highly significant for both bowel cancer and angina vignettes (p<.001). For the former vignette, there was also a statistically significant difference between urgency ratings for the groups who correctly identify the cause and those who approximated the cause (p<.001).

Impact of seriousness rating on urgency of help-seeking

For all vignettes there was a statistically significant (p<.001) Spearman rank order correlation between ratings of seriousness and urgency. The more serious the symptoms were perceived to be, the more quickly help would be sought. For the 'joint pain and stiffness' vignette, the correlation between seriousness and urgency ratings was 0.729; when 'swelling was added' it was 0.811 and for symptoms in 'feet and ankles' 0.825. The correlation for bowel cancer was 0.846, and for angina 0.882.

DISCUSSION

Both the interview and survey data showed marked differences between symptom recognition for angina, bowel cancer and RA. Participants were less likely to recognise the symptoms of RA and often assigned these symptoms to less serious or non-modifiable (e.g. 'old age') causes. This effect was more pronounced when the symptoms did not include joint swelling. In contrast, the symptoms of bowel cancer and angina were more readily recognised and were considered to be more serious.
Role of symptom recognition in help-seeking for RA

than those of RA. Respondents would seek help faster for the symptoms of bowel cancer or angina compared to symptoms of RA. Correct and approximate causal attributions of symptoms had more effect on perceived urgency of help-seeking for angina and bowel cancer than it had for any of the RA vignettes. There was a significant correlation between urgency and seriousness ratings for all vignettes, however the correlation for the RA vignette was slightly lower than for angina or bowel cancer.

The interview and survey data clearly show that in line with expectations, accurate symptom recognition and perceived seriousness are both associated with speedy help-seeking. This was the case for all the symptom vignettes, although the correlations between the urgency and serious ratings for the RA vignettes were somewhat lower than those for angina and bowel cancer. In addition to this, the causal attribution did not have such a clear-cut effect on the urgency of seeking medical attention for RA symptoms compared to bowel cancer and angina. One potential explanation in the context of the RA vignettes is that people may feel that not much can be done for the symptoms of RA or that speed is not required despite perceived seriousness due to a perception that the symptoms will not worsen if left unaddressed. Some of the quotes from the interviews seem to support this speculation (e.g.T1Q11).

The interview data further suggest that specific features related to the onset of RA symptoms (sudden onset vs slow progression; widespread vs localised etc.) impact on how serious they are considered to be and how urgently help would be sought (see also Supplementary Table 4, quote 6). This is consistent with the survey data.
Role of symptom recognition in help-seeking for RA

and with previous research (16, 17). Pelaez and colleagues suggest that there are three trajectories of help-seeking that RA patients might follow depending on whether there is a rapid symptom onset, oscillating symptom onset or slow gradual onset of symptoms. The latter two trajectories are associated with delayed help-seeking, and help-seeking from non-medical sources, such as social networks (16).

The fact that help seeking would be delayed with slow onset of symptoms is particularly worrying as only around 15% of RA patients have an acute onset of symptoms (27). In this study we have sought to understand determinants of the speed help seeking in the context of RA in relation to two other common and serious diseases.

Both the interview and survey data showed marked differences between symptom recognition for angina, bowel cancer and RA. Participants were less likely to recognise the symptoms of RA and often assigned these symptoms to less serious or non-modifiable (e.g., ‘old age’) causes. This effect was more pronounced when the symptoms did not include joint swelling. In contrast, the symptoms of bowel cancer and angina were more readily recognised and were considered to be more serious than those of RA. Respondents reported the intention to seek help faster for the symptoms of bowel cancer or angina compared to symptoms of RA. Correct and approximate causal attributions of symptoms had more effect on perceived urgency of help-seeking for angina and bowel cancer than it had for any of the RA vignettes.

There was a significant correlation between urgency and seriousness ratings for all vignettes, however the correlation for the RA vignettes was slightly lower than for angina or bowel cancer.
Role of symptom recognition in help-seeking for RA

The interview and survey data clearly show that in line with expectations, accurate symptom recognition and perceived seriousness are both associated with the intention to seek help urgently. This was the case for all the symptom vignettes, although the correlations between the urgency and serious ratings for the RA vignettes were somewhat lower than those for angina and bowel cancer. In addition to this, the causal attribution did not have such a clear-cut effect on the urgency of seeking medical attention for RA symptoms compared to bowel cancer and angina. One potential explanation in the context of the RA vignettes is that people may feel that not much can be done for the symptoms of RA or that speed is not required despite perceived seriousness due to a perception that the symptoms will not worsen if left unaddressed.

The interview data further suggest that specific features related to the onset of RA symptoms (sudden onset vs slow progression; widespread vs localised etc.) impact on how serious they are considered to be and how urgently help would be sought (see also Supplementary Table 4, quote 6). This is consistent with the survey data and with previous research (16;17).

Previous research has shown that health campaigns such as BCOC can aid symptom recognition and increase appropriate help-seeking (19;28). A number of our interviewees spontaneously mentioned having seen the BCOC campaign for bowel cancer and correctly identified the symptoms described in the vignette (see also Supplementary Table 4, quotes 11 and 12).
Role of symptom recognition in help-seeking for RA

The current research has a number of limitations. Firstly, as with most biomedical research, only those individuals who consented to participate were included. Research has shown that people take part in health research for a variety of reasons including altruism and a desire to gain more information about the subject matter of the research (29). These motivations will have an effect on the type of people taking part, the replies to the survey and the themes discussed in the interviews. For example, the large proportion of interviewees and survey respondents reporting joint problems themselves might be a result of a motivation to find out more information about (rheumatoid) arthritis. Secondly, although they formed a substantial part of the group of potential participants invited for this study, very few participants from an ethnic minority background chose to participate in either study. It is well recognized that ethnic minority groups are often under-represented in health studies (30). A combination of factors have been suggested as barriers to participation, including language barriers, financial difficulties, fear of stigmatization and a mistrust of research or health professionals (31) and future studies should specifically aim to address these issues in order to explore the views of minority groups.

Thirdly although, in the interviews we alternated with the ordering of the RA vignettes and the bowel cancer and angina vignettes, this was not done in the survey which had a single format. There is the potential that having the RA vignettes first in the survey influenced the subsequent ratings for the non-RA vignettes.

The hypothetical approach taken within these two studies (participants are asked to imagine what they would do when encountering certain symptoms) can be considered both a strength and a weakness. Asking members of the general public to react to a number of prospective scenarios is as close as we can get to the
Role of symptom recognition in help-seeking for RA

experiences of patients who have just started to experience symptoms. This latter group is difficult to assess precisely for the reason which inspired the current research, patients rarely see their GP within weeks of symptom onset (17). Studying intentions is valuable where it is difficult to access actual behavior (REF). However, whether the intended behaviour as described by our participants in reaction to the vignettes would translate into actual behaviour if they were ever confronted with any of the symptoms in 'real life' depends on many factors including how much control they feel they have of the situation at the time (32). It was not possible to measure these factors with the current research design.

The current findings from the interviews and the survey extend those identified in previous qualitative research. (REF). Themes found in the qualitative data from the interviews were quantified and supported through the findings of the survey. Although the response rate for the survey was relatively low, the consistency between the quantitative data and the interview data are a good indication that the combined findings reflect the perceptions of the wider general public.

The evidence presented here demonstrates that the general public are less likely to make a correct causal attribution for the symptoms of RA, and less likely to perceive RA symptoms to be serious and to require urgent help compared with other common and serious conditions. This highlights a need to raise awareness about the symptoms of RA, the potential negative impact of RA on quality of life, and the importance of early help-seeking (5;7-10).

<table>
<thead>
<tr>
<th>Quotes illustrating perceived seriousness of RA symptoms</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. “Well, 65 plus, if it’s any younger than that, well then it, it’s even more, serious, if serious is the right word to use but something is wrong, and it’s not just, antiquity.” (p04)</td>
</tr>
<tr>
<td>2. “it doesn’t seem to me that this is (serious), this could possibly be, … I wouldn’t say well that’s something that could be really bad it just sounds like something a lot of people have therefore it would have to be – it would have to be getting progressively worse for me to get medical attention” (p07)</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Quotes illustrating perceived seriousness of bowel cancer symptoms</th>
</tr>
</thead>
<tbody>
<tr>
<td>3. “Well (if) I had blood in, in my toilet, I would think it’s serious” (p29)</td>
</tr>
<tr>
<td>4. “Oh well, …just like a tummy upset or something like that I would rule that out. It’s more serious than that if it’s ongoing. Particularly if I’ve … lost weight and there’s no change in my diet. And I’ve not been in contact with anybody who had an upset stomach” (p24)</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Quotes illustrating perceived seriousness of angina symptoms</th>
</tr>
</thead>
<tbody>
<tr>
<td>5. “Well, I think if it’s your chest or your lungs or whatever, anyway, …it’s pretty serious anyway, isn’t it, …so it’s something that you don’t muck about with really, or it’s things for concern at the end of the day…” (p12).</td>
</tr>

</table>
| 6. “That they (symptoms) are quite common, that they’re not debilitating, there seems to be a condition that you can live with, you should be able
Role of symptom recognition in help-seeking for RA

to manage quite easy." (p07)

“I don’t think I would leave that for any, any length of time. If I saw that
the joints were swollen I think… I would be concerned, and – I suppose
you’d wait, initially, because …you may think, ‘Oh, well, it could have
been…a knock’ or whatever it might be. But if you could see…there
were various joints affected, then I would be, I think, making an
appointment to see the GP (Family practitioner)...” (p11)

Quotes illustrating perceived urgency of help-seeking for bowel cancer
symptoms

“No if I saw that this morning I’d be banging on the doctors door.” (p07)

“Well if I notice it for a few days I will go to my GP (Family practitioner)
because… it’s, obviously if I want to take my weight that might take me a
few weeks to notice change in my …….but if I’m feeling tired, run down,
lethargic and there’s a change in my bowel habit with blood in my stool I
probably would not wait for the weight loss, I probably would go say look
something is going on here, I don’t know what it is” (p05).

Quotes illustrating perceived urgency of help-seeking for angina symptoms

“Well if it was severe I’d pick up the phone and dial 999 or ask
somebody else to do it if it was really, really severe, but … I would sort of
basically take it easy, I’d sort of relax, put my feet up and sort of monitor
the situation … to see how it is, does it seem a little bit better or does it
seem it’s … just as bad.” (p14)

“Well it depends as I say how many times, I think probably give it a
month maybe, unless they were coming regularly not just a one off every
Role of symptom recognition in help-seeking for RA

now and again you might put it down to something else." (p03)

Quote illustrating comparison of urgency across conditions

2412 “So it could have been a month. It could be two months with it (RA
Symptoms) …. I don’t think I’d be as quick going as what I would with
those…With the cancer and…the heart and the other one. No, I wouldn’t,
I wouldn’t be as quick going (with RA symptoms). This would probably –
what – about two or three months, I suppose before you’d really … Just
how long you could stand the pain for.” (p10)
Table 3. *Seriousness and urgency ratings.* Median (Interquartile range (IQR)) values shown. Lower scores indicate greater levels of seriousness and urgency.

Rank-based nonparametric Kruskal-Wallis Test was used to determine if there were significant differences in speed with which help would be sought between groupings of causal attributions; two-way comparisons were subsequently used to directly compare correct attribution with approximate and incorrect attributions. A Bonferroni adjustment has been applied to the \( p\text{-adj} \) values for the pairwise comparisons.
Figure 1: Distribution of ratings of seriousness of the symptoms of RA joint pain and joint stiffness in hands and wrists (a), RA joint pain, stiffness and swelling in hands and wrists (b), RA joint pain, stiffness and swelling in the feet and ankles (c), bowel cancer and angina by survey respondents.
