Thermoregulation During Intermittent Exercise in Athletes With a Spinal-Cord Injury

Katy E. Griggs, Christof A. Leicht, Michael J. Price, and Victoria L. Goosey-Tolfrey

**Purpose:** Individuals with a spinal-cord injury (SCI) have impaired thermoregulatory control due to a loss of sudomotor and vasomotor effectors below the lesion level. Thus, individuals with high-level lesions (tetraplegia) possess greater thermoregulatory impairment than individuals with lower-level lesions (paraplegia). Previous research has not reflected the intermittent nature and modality of wheelchair court sports or replicated typical environmental temperatures. Hence, the purpose of this study was to investigate the thermoregulatory responses of athletes with tetraplegia and paraplegia during an intermittent-sprint protocol (ISP) and recovery in cool conditions. **Methods:** Sixteen wheelchair athletes, 8 with tetraplegia (TP, body mass 65.2 ± 4.4 kg) and 8 with paraplegia (body mass 68.1 ± 12.3 kg), completed a 60-min ISP in 20.6°C ± 0.1°C, 39.6% ± 0.8% relative humidity on a wheelchair ergometer, followed by 15 min of passive recovery. Core temperature ($T_{core}$) and mean ($T_{sk}$) and individual skin temperatures were measured throughout. **Results:** Similar external work ($P = .70, ES = 0.20$) yet a greater $T_{core}$ ($P < .05, ES = 2.27$) and $T_{sk}$ ($P < .05, ES = 1.50$) response was demonstrated by TP during the ISP. **Conclusions:** Despite similar external work, a marked increase in $T_{core}$ in TP during exercise and recovery signifies that thermoregulatory differences between the groups were predominantly due to differences in heat loss. Further increases in thermal strain were not prevented by the active and passive recovery between maximal-effort bouts of the ISP, as $T_{core}$ continually increased throughout the protocol in TP.

**Keywords:** thermoregulatory, intermittent-sprint exercise, wheelchair sport, tetraplegia, paraplegia.

Individuals with a spinal-cord injury (SCI) have reduced afferent information to the thermoregulatory center\(^1\)\(^2\) and a loss of both sweating capacity and vasomotor control below the level of the spinal lesion.\(^1\)\(^3\)\(^4\) As blood-flow redistribution and sweating are 2 major thermoregulatory effectors, this suggests that individuals with an SCI have compromised thermoregulation and are at a greater risk of heat illness than able-bodied individuals.\(^5\)

The magnitude of the thermoregulatory impairment in those with an SCI is proportional to the level of the lesion.\(^1\)\(^2\)\(^3\)\(^4\) As blood-flow redistribution and sweating are 2 major thermoregulatory effectors, this suggests that individuals with an SCI have compromised thermoregulation and are at a greater risk of heat illness than able-bodied individuals.\(^5\)

Purpose: Individuals with a spinal-cord injury have impaired thermoregulatory control due to a loss of sudomotor and vasomotor effectors below the lesion level. Thus, individuals with high-level lesions (tetraplegia) possess greater thermoregulatory impairment than individuals with lower-level lesions (paraplegia). Previous research has not reflected the intermittent nature and modality of wheelchair court sports or replicated typical environmental temperatures. Hence, the purpose of this study was to investigate the thermoregulatory responses of athletes with tetraplegia and paraplegia during an intermittent-sprint protocol (ISP) and recovery in cool conditions. Methods: Sixteen wheelchair athletes, 8 with tetraplegia (TP, body mass 65.2 ± 4.4 kg) and 8 with paraplegia (body mass 68.1 ± 12.3 kg), completed a 60-min ISP in 20.6°C ± 0.1°C, 39.6% ± 0.8% relative humidity on a wheelchair ergometer, followed by 15 min of passive recovery. Participants
Eight wheelchair rugby players with TP (7 men, 1 woman, 1 incomplete lesion)\(^1\)\(^2\) and 8 wheelchair basketball players with PA (7 men, 1 woman, 3 incomplete lesions)\(^1\)\(^2\) (Table 1), gave their written informed consent to participate in this experimental research study. The study was approved by the university research ethics committee and was conducted in accordance with the Declaration of Helsinki.

**Methods**

Participants
Eight wheelchair rugby players with TP (7 men, 1 woman, 1 incomplete lesion)\(^1\)\(^2\) and 8 wheelchair basketball players with PA (7 men, 1 woman, 3 incomplete lesions)\(^1\)\(^2\) (Table 1), gave their written informed consent to participate in this experimental research study. The study was approved by the university research ethics committee and was conducted in accordance with the Declaration of Helsinki.

**Preliminary Tests**

On arrival at the laboratory, skinfold measurements were taken from the biceps, triceps, subscapular, suprailiac, and abdomen, followed...
by a continuous incremental test on a treadmill to determine peak oxygen uptake (VO\textsubscript{2peak}). For the VO\textsubscript{2peak} test, participants were set up in their own sports wheelchair and mounted on the treadmill; workload was increased by 0.2 or 0.3 m/s every 3 minutes (dependent on the individual’s classification) until the participant could no longer maintain the speed of the treadmill.

### Experimental Conditions

Participants ingested a telemetry pill (HQ Inc, Palmetto, Florida) for the measurement of core temperature (\(T_{\text{core}}\)) ~8 hours before the start of the test to avoid the influence of ingested food or fluid on the temperature reading. Two hours after the preliminary test, participants were weighed (Marsden Weighing Group Ltd, Henley-on-Thames, UK) with no clothing covering their upper body. During the intermittent-sprint protocol (ISP) participants wore their usual training attire of lightweight tracksuit trousers and either a short- or long-sleeved top. Seven thermistors (Grant Instruments, Cambridge, UK) were attached to the skin using strips of water-permeable surgical tape (3M Transpore, Loughborough) placed on the right side of the body on the forehead, forearm, biceps, upper back, chest, thigh, and calf for measurement of skin temperature (Grant Squirrel logger, Series 2010, Grant Instruments, Cambridge, UK). Mean skin temperature (\(T_{\text{sk}}\)) was estimated in accordance with the formula by Ramanathan. Heat storage was calculated using the following formula\textsuperscript{14}:

\[
\text{Heat storage} = (0.8 \Delta T_{\text{core}} + 0.2 \Delta T_{\text{sk}}) \times c_b
\]

where \(c_b\) is the specific heat capacity of the body tissue (3.49 J \cdot g\textsuperscript{-1} \cdot \degree C\textsuperscript{-1}) and \(\Delta T_{\text{core}}\) and \(\Delta T_{\text{sk}}\) represent changes in \(T_{\text{core}}\) and \(T_{\text{sk}}\) from rest to the end of each exercise block and recovery. An estimate of external work was calculated by total distance covered (m) during the ISP multiplied by total resistance (N) of the ergometer-wheelchair system.

After instrumentation and transfer to their own sports wheelchair, participants rested for 10 minutes before completing a self-selected warm-up on a single-cylinder wheelchair ergometer (WREG, Bromakin, Loughborough, UK).\textsuperscript{15} During the warm-up, they performed a deceleration test for power and resistance to be calculated.\textsuperscript{16}

The ISP was conducted in an environmental chamber at 20.6°C ± 0.1°C and 39.6% ± 0.8% relative humidity, chosen to replicate a sports-hall environment. All participants completed the test at a similar time in the afternoon to negate circadian variation, and they refrained from caffeine and alcohol 24 hours before the test. The ISP simulated an on-court session and is reported elsewhere.\textsuperscript{17} Briefly, it consisted of 4 exercise blocks separated by 4.5 minutes of passive recovery (Figure 1). Each block comprised 6 bouts of 30 seconds, where athletes performed alternately 3 pushes forward and backward for the first 15 seconds followed by a 15-second sprint at maximum effort. Bouts were followed by 90 seconds of active recovery at low intensity. At the end of block 4, participants rested for 15 minutes before all thermistors were removed and they were reweighed. The whole session lasted 55.5 minutes, with maximum-intensity activity accounting for 12 minutes, including a total of 24 sprints. Verbal encouragement was given throughout the test.

Heart rate (HR) was recorded at 5-second intervals during the ISP (Polar PE 4000, Kempele Finland). Whole-body rating of perceived exertion\textsuperscript{18} and thermal sensation\textsuperscript{19} were recorded at the end of each exercise block. Before the start of the ISP and during recovery, thermal sensation was also recorded. The thermal-sensation scale comprised categories ranging from 0 (unbearably cold) to 8 (unbearably hot). After the warm-up and on completion of exercise, capillary blood samples were taken from the earlobe and analyzed for hematocrit (Haemotospin 1300, Hawksley, Lancing, UK) and hemoglobin (B-Hemoglobin, Hemocue Ltd, Dronfield, UK) to determine plasma volume.\textsuperscript{20} Capillary blood samples were taken at the end of each block for analysis of blood lactate concentration (YSI Sport, YSI Inc, OH, USA). Participants were allowed to drink ad libitum during the passive recovery between blocks.

### Statistical Analysis

All data were checked for normality, using the Shapiro–Wilk test. Delta core and skin temperatures were calculated. Independent \(t\) tests were used to analyze any between–groups differences in participant characteristics, total distance, total resistance, external work, fluid balance, and start and end \(T_{\text{core}}\), \(T_{\text{sk}}\), and heat storage. Sprint speed and power output across the 24 sprints and physiological and thermoregulatory responses were analyzed using a 2-way (group × time) analysis of variance (ANOVA). Where significance was obtained, post hoc pairwise comparisons with a Bonferroni correction were conducted. For individual skin temperatures and heat storage during recovery, data from 7 athletes with TP were used, as data from the last 3 minutes of recovery were missing for 1 participant. For all comparisons where the assumption of sphericity was violated, a Greenhouse–Geisser correction was applied. Effect sizes (ES) were estimated by Cohen \(d\), where 0.2 represented a small effect size, 0.5 a medium effect size, and 0.8 a large effect size.\textsuperscript{21} All data were analyzed using SPSS version 19.0, and significance was accepted at the \(P \leq .05\) level.

### Results

#### Participant Characteristics

There were no differences between TP and PA for the physiological and participant characteristics (\(P > .05\), Table 1), yet large effect sizes were apparent for VO\textsubscript{2peak} (ES = 0.89) and training hours per week (ES = 0.73).

#### Sprint Performance

There were no differences between groups or across the 24 sprints for either sprint speed or peak power output (all \(P > .05\), Table 2). Total resistance of the ergometer-wheelchair system was greater in TP (\(P = .01\), ES = 1.64), while total distance covered during the ISP was greater for PA (\(P < .001\), ES = 1.92). External work was not statistically different between groups (\(P = .70\), ES = 0.20).
Physiological Responses

Mean and peak HR for each block of the ISP were greater for PA than TP ($P < .05$, Table 3). Mean HR for both groups increased from block 1 to 2 and then remained stable throughout exercise. For both groups peak HR was similar over time ($P = .43$). Throughout exercise, blood lactate was similar over time ($P = .09$) but different between groups (8.08 ± 3.04 and 8.73 ± 2.17 mmol/L for TP and PA, respectively, $P = .02$, ES = 0.25).

Core Temperature

$T_{\text{core}}$ was similar between groups at the start of exercise (37.0°C ± 0.6°C and 37.1°C ± 0.3°C for TP and PA, respectively, $P = .75$, ES = 0.16). At the end of exercise TP demonstrated a greater $T_{\text{core}}$ than PA (38.2°C ± 0.5°C and 37.6°C ± 0.4°C for TP and PA, respectively, $P = .02$, ES = 1.32). During both exercise and recovery, TP experienced a greater increase in $T_{\text{core}}$ from resting values than PA (both $P < .001$, ES = 0.75 and ES = 2.27 for exercise and recovery, respectively, Figure 2). At the end of recovery, $T_{\text{core}}$ for TP remained elevated from rest by 1.1°C compared with 0.2°C for PA (38.1°C ± 0.5°C and 37.3°C ± 0.3°C for TP and PA, respectively, $P < .001$, ES = 1.84).

Skin Temperature

$T_{\text{sk}}$ was similar between groups at the start (29.5°C ± 0.6°C and 30.6°C ± 0.6°C for TP and PA, respectively, $P = .09$, ES = 0.91) and end of exercise (30.2°C ± 1.5°C and 30.0°C ± 1.6°C for TP and PA, respectively, $P = .75$, ES = 0.16) and end of recovery (30.0°C ± 1.4°C and 29.7°C ± 1.8°C for TP and PA, respectively, $P = .76$, ES = 0.16). During exercise and recovery the change in $T_{\text{sk}}$ from resting values was different between TP and PA ($P < .001$, ES = 1.50, $P = .02$, ES = 2.27).
Griggs et al

472

= 1.43 for exercise and recovery, respectively). For the PA group, 
$T_{uk}$ decreased during exercise, while athletes with TP experienced 
an increase in $T_{uk}$ (Figure 2). Individual skin temperatures (Figure 3) 
were similar between groups at the start and end of exercise ($P > .05$).

During exercise, back skin temperature was the only site that dem-

onstrated a difference between groups, with an increase from resting 
values in TP (0.9°C ± 0.6°C) and a decrease in PA (–0.4°C ± 0.9°C, 
$P < .001$, ES = 1.65). During recovery, chest, back, forearm, and 
forehead skin temperature remained elevated from start-of-recovery 
values to a greater extent in TP than PA ($P < .05$).

**Heat Storage**

Heat storage was greater in TP (2.8 ± 1.2 J/g) than PA (1.0 ± 1.0 
J/g) during exercise (Figure 4, $P < .001$, ES = 1.61) and at the end 
of recovery (3.4 ± 1.4 J/g and –0.5 ± 1.3 J/g for TP and PA, respec-
tively, $P < .001$, ES = 3.08).

**Perceptual Measures**

During exercise, rating of perceived exertion was similar between 
groups ($P = .52$, ES = 0.24), with an increase over time (14 ± 1 
and 16 ± 2 for the end of blocks 1 and 4, respectively). Thermal sensation 
was similar between groups during exercise, (4 ± 1 and 6 ± 1 at rest 
and end of block 4, respectively, $P = .29$, ES = 0.31) and recovery 
(6 ± 1 and 3 ± 1 at the start and end of recovery, respectively, $P = 
.69$, ES = 0.14).

**Fluid Balance**

Both TP and PA drank similar amounts during the ISP and recovery 
(540 ± 112 and 469 ± 233 mL for TP and PA, respectively, $P = .45$, 
ES = 0.39). The change in body mass (0.4 ± 0.4 and 0.1 ± 0.3 kg 
for TP and PA, respectively, $P = .11$, ES = 0.84) and plasma volume 
changes were similar between groups (4.0% ± 13.7% and 4.3% ± 9.5% 
for TP and PA, respectively, $P = .96$, ES = 0.03).
Discussion

The main findings indicate that despite external work being similar between groups, $T_{core}$ and heat storage increased at a greater magnitude in TP compared with PA during intermittent-sprint exercise in cool conditions. The greater increase in $T_{core}$ for TP signifies that thermoregulatory differences between the groups were predominantly due to a lower capacity for heat loss in TP than in PA. Even during postexercise recovery, $T_{core}$ and heat storage remained elevated in TP, signifying an inability to dissipate the heat produced during exercise, resulting in the retention of heat during recovery.

Figure 3 — Individual (A) back, (B) upper-arm, (C) calf, and (D) thigh skin temperatures for athletes with tetraplegia (TP) and athletes with paraplegia (PA) during each exercise block (E) and recovery (R). *Significantly different from PA ($P < .05$).

Figure 4 — Heat storage for athletes with tetraplegia (TP) and athletes with paraplegia (PA) during each exercise block and recovery. *Significantly different from PA ($P < .05$).
Further increases in thermal strain in TP were not prevented by the active and passive recovery between the maximum-effort bouts, as $T_{\text{core}}$ and heat storage were found to continually increase throughout the protocol in this group. The $T_{\text{core}}$ responses for both groups are therefore comparable to those in previous studies during continuous wheelchair exercise, with increases of $0.2^\circ \text{C}$ to $0.7^\circ \text{C}$ and $0.9^\circ \text{C}$ observed for PA and TP, respectively.

The $T_{sk}$ response of the 2 groups likely reflects the athletes’ sweating capacity, being proportional to lesion level. For instance, the greater reduction in sweating capacity in TP resulted in an increase in $T_{sk}$ during exercise. In PA, $T_{sk}$ decreased during exercise, likely due to the larger body-surface area available for sweating and therefore greater evaporative cooling of the skin. It should be noted that although $T_{sk}$ was not significantly different at the onset of exercise, a large ES demonstrates that PA may have had a substantially warmer starting $T_{sk}$ than TP. Nonetheless, $T_{sk}$ data should be interpreted with caution in individuals with a SCI, as it may mask regional skin-temperature responses.

During exercise, differing responses in back skin temperature were apparent, increasing in TP and decreasing in PA, due to the majority of the upper-body skin of TP being insensitive compared with sensitive in PA. However, a similar finding was not found for chest skin temperature. Sweat rates vary with body region in able-bodied individuals, with a greater sweat rate apparent at the upper back than the chest. Therefore, at the chest, a lower evaporative cooling effect of sweat may have been apparent in PA, resulting in a chest skin temperature similar to that seen in TP. In both groups, upper-arm skin temperature demonstrated a decrease during exercise shown previously, yet more pronounced during continuous wheelchair propulsion.

The decrease in upper-arm skin temperature is thought to be caused by the arm moving relative to the body in wheelchair propulsion, causing convective cooling to the upper arm.

Neither group experienced a change in thigh skin temperature during exercise or recovery, likely due to the disrupted blood flow and vascular atrophy below the level of the lesion. Although small, there was a significant increase from rest in calf skin temperature over time, possibly due to the variable response of calf skin temperature in PA. A greater increase in calf skin temperature than the current study was previously observed during prolonged arm cranking, leading those authors to suggest that the lower body is a potential site for heat storage in PA. The degree of sweating and blood-flow redistribution in the lower limb may be dependent on the lowest intact part of the sympathetic chain, with the pathway for vasodilation in the lower limb located at or below T10. In individuals with lesions at T12, calf skin temperature has been shown to increase during exercise, with little or no change for individuals with lesions at T10–T11. However, in the current study, similar trends in calf skin temperature were apparent for individuals with lesions above (n = 5) and below T10 (n = 3) in the PA group. To fully understand the underlying mechanisms of vasomotor control of the lower body during upper-body exercise, further study is required.

More pronounced differences between skin-temperature sites may have been masked by the large interindividual variations in skin temperatures, a noticeable response in studies in the SCI population. These variations may have been heightened by the large range of lesion levels in PA (T4–S1), resulting in differences in sympathetic and somatosensory pathways, in arrangements of sympathetic outflow and the type and degree of reinnervation.

From a perceptual perspective, even though the TP group was interpreted with caution in individuals with a SCI, as it may mask regional skin-temperature responses. From a perceptual perspective, even though the TP group was trained to be warmer. This may be related to training status, with potentially a greater $T_{\text{core}}$ being better tolerated by the highly trained. Although not significant, a large ES in training hours (ES = 0.73) signifies that the TP participants in the current study were more highly trained and hence may have a better tolerance of greater $T_{\text{core}}$ values. Due to the smaller surface area of sensitive skin in TP than in PA, it is also possible that TP may not perceive the increase in body temperature as effectively. During higher-intensity exercise and in warmer ambient conditions, this may be of more concern, especially as these athletes could potentially override perceived signs of thermal strain, putting themselves at risk for heat illness.

The training status of the athletes with TP may have led to a greater development of their remaining musculature. Potentially, this may have enabled them to produce power outputs and external work similar to those with PA. The larger total resistance of the ergometer-wheelchair system for TP was, however, likely caused by the differences in the mass of the wheelchairs used in wheelchair basketball and rugby, with heavier wheelchairs used in the latter (~11–13 vs 15–19 kg). The lower mean and peak HR in TP, due to the reduced sympathetic innervation of the heart, is consistent with previous studies. Although there was no significant difference in VO$_{2\text{peak}}$, a large ES signifies a meaningful difference between the groups, with previous research indicating an inverse relationship between lesion level and VO$_{2\text{peak}}$. The extent to which the athletes’ aerobic fitness would have affected the results is unclear, yet future work matching the groups for training status may accentuate the differences in thermoregulatory responses due to the level of spinal lesion.

**Practical Applications**

Although neither group was under considerable thermal strain, the current study highlights that athletes with TP experience a greater increase in $T_{\text{core}}$ for the same external work load of intermittent-sprint exercise than those with PA. Even though the protocol had greater ecological validity than previous studies due to the intermittent nature and use of wheelchair propulsion, the ISP may not have been wholly reflective of a wheelchair basketball or rugby match. Total distances covered were considerably shorter (2316 m) than the activity profiles of wheelchair rugby players during a match (4540 m). If the ISP were of a magnitude similar to that of match play, that is, greater metabolic work, the athletes may have experienced a greater thermal response, especially those with TP. Practically, support staff should closely monitor athletes with TP for signs of heat stress during wheelchair court sports and, if possible, apply appropriate cooling before, during, or after play.

A limitation of the study may be the inclusion of 4 individuals with an incomplete SCI (1 TP and 3 PA) in the mean group values. The degree of autonomic dysfunction may depend on the completeness of the injury, with incomplete lesions resulting in a greater amount of sensory information regarding one’s thermal state and a greater capacity to sweat. Nevertheless, their inclusion was justified, as their $T_{\text{core}}$ and $T_{sk}$ responses were within 1 SD of the mean response of each group.

**Conclusion**

Similarly to continuous arm-cranking and wheelchair exercise, athletes with TP have a greater inability to dissipate heat than those with PA during intermittent-sprint exercise in cool conditions. Despite the 2 groups’ producing similar amounts of external work, the TP group had a marked increase in $T_{\text{core}}$ during exercise.
and recovery, signifying that differences between the groups were predominantly due to differences in heat loss. Neither group was under high levels of thermal strain, yet the current study highlights the heightened thermal response of athletes with TP to intermittent wheelchair exercise, with caution that a greater $T_{core}$ response may be apparent during actual game play. Support staff should be aware of the greater thermal impairment experienced by those with TP in wheelchair court sports, monitor them for signs of heat stress, and, if possible, apply appropriate cooling before, during, or after play.

Acknowledgments

The authors would like to thank GBWR and the Great Britain Wheelchair Basketball Association for their support and participation in the current study. Also we thank Jessica Lavin (formerly School of Sport, Exercise and Health Sciences, Loughborough University) and Dr John Lenton (Peter Harrison Centre for Disability Sport, School of Sport, Exercise and Health Sciences, Loughborough University) for their assistance during data collection, Craig Boyd (Faculty of Health and Wellbeing, Sheffield Hallam University) for the loan of equipment, Prof George Havenith (Design School, Loughborough University) for his guidance on the study, and Dr Steve Faulkner for proofreading the manuscript (School of Sport, Exercise and Health Sciences, Loughborough University).
